Tidy Data

Introduction

In this calpter, you will learn a consistent way to organise your data in R, and organization called **tidy data**. Getting you data into this format requires some upfront work, but that work pays off in the long term.

Prerequisites

In this chapter we'll focus on tidyr, a package that provides a bunch of tools to help tidy up your messy datasets. tidyr is a member of the core tidyverse

library(tidyverse)

```
----- tidyverse 1.3.2 --
## -- Attaching packages -----
## v ggplot2 3.4.0
                      v purrr
                                1.0.1
## v tibble 3.1.8
                      v dplyr
                                1.1.0
## v tidyr
            1.3.0
                      v stringr 1.5.0
## v readr
            2.1.3
                      v forcats 1.0.0
## -- Conflicts ---
                                              ----- tidyverse_conflicts() --
## x dplyr::filter() masks stats::filter()
## x dplyr::lag()
                    masks stats::lag()
```

Tidy Data

You can represent the same underlying data in multiple ways. The example below shows the same data organized in four different ways. Each dataset shows the same values for four variables *country*, *year*, *population*, and *cases*, but each dataset organizes the values in a different way. Table 1

table1

```
## # A tibble: 6 x 4
##
     country
                   year
                          cases population
##
     <chr>>
                          <dbl>
                                      <dbl>
                  <dbl>
## 1 Afghanistan
                   1999
                            745
                                  19987071
## 2 Afghanistan
                   2000
                           2666
                                  20595360
## 3 Brazil
                   1999
                         37737
                                 172006362
```

```
## 4 Brazil 2000 80488 174504898
## 5 China 1999 212258 1272915272
## 6 China 2000 213766 1280428583
```

Table 2

table2

```
## # A tibble: 12 x 4
##
         country year type
                                                           count
         <chr>
                          <dbl> <chr>
##
                                                           <dbl>
## 1 Afghanistan 1999 cases
                                                              745
## 2 Afghanistan 1999 population
                                                     19987071
## 3 Afghanistan 2000 cases
                                                            2666
## 4 Afghanistan 2000 population
                                                     20595360
## 5 Brazil 1999 cases 37737

## 6 Brazil 1999 population 172006362

## 7 Brazil 2000 cases 80488

## 8 Brazil 2000 population 174504898

## 9 China 1999 cases 212258

## 10 China 1999 population 1272915272

## 11 China 2000 cases 213766
## 12 China
                            2000 population 1280428583
```

Table 3

table3

Table 4a

table4a

Table 4b

table4b

```
## # A tibble: 3 x 3
     country
                                  '2000'
##
                      '1999'
##
     <chr>>
                       <dbl>
                                   <dbl>
## 1 Afghanistan
                               20595360
                    19987071
## 2 Brazil
                   172006362 174504898
## 3 China
                  1272915272 1280428583
```

There are three interrelated rules which make a dataset tidy: 1. Each variable must have its own column 2. Each observation must have its own row 3. Each value must have its own cell

These rules are interrelated because it's impossible to only satisfy two of the three. That interrelationship leads to an even simpler set of practical instructions: 1. Put each dataset in a tibble 2. Put each variable in a column

Exercises

1. Compute the *rate* for table 2.

```
table2_cases <- table2 %>%
  filter(type == "cases")

table2_population <- table2 %>%
  filter(type == "population")

table2_mod <- tibble(
  country = table2_cases$country,
  year = table2_cases$year,
  cases = table2_cases$count,
  population = table2_population$count
)</pre>
```

```
##
        country year cases population
## [1,]
           TRUE TRUE TRUE
                                  TRUE
## [2,]
           TRUE TRUE TRUE
                                  TRUE
## [3,]
           TRUE TRUE TRUE
                                  TRUE
## [4,]
           TRUE TRUE
                      TRUE
                                  TRUE
## [5,]
           TRUE TRUE
                      TRUE
                                  TRUE
## [6,]
           TRUE TRUE TRUE
                                  TRUE
```

```
table2_mod %>%
  mutate(rate = (cases / population) * 10000)
```

```
## 3 Brazil 1999 37737 172006362 2.19
## 4 Brazil 2000 80488 174504898 4.61
## 5 China 1999 212258 1272915272 1.67
## 6 China 2000 213766 1280428583 1.67
```

Pivoting

For most real analyses, you'll need to do some tidying.

- 1. One variable might be spread across multiple columns
- 2. One observation might be scattered across multiple rows

To fix these problems, you'll need the two most important functions in tidyr: $pivot_longer()$ and $pivot_wider()$

pivot_longer()

To tidy a dataset like this, we need to pivot the offending columns into a new pair of variables. To describe that operation we need three parameters.

- The set of columns whose names are values, not variables. In this example, those are the columns 1999 and 2000.
- The name of the variable to move the column names to. Here it is year
- The name of the variable to move the column values to. Here it is cases

```
table4a %>%
  pivot_longer(c(`1999`, `2000`), names_to = "year", values_to = "cases")
```

```
## # A tibble: 6 x 3
##
     country
                 year
                         cases
##
     <chr>
                 <chr>
                         <dbl>
## 1 Afghanistan 1999
                           745
## 2 Afghanistan 2000
                          2666
## 3 Brazil
                 1999
                         37737
## 4 Brazil
                 2000
                         80488
## 5 China
                 1999
                        212258
## 6 China
                 2000 213766
```

pivot_longer() makes data sets longer by increasing the number of rows and decreasing the number of columns.

Tidy table 4b

```
table4b %>%
  pivot_longer(c(`1999`, `2000`), names_to = "year", values_to = "population")
```

```
## # A tibble: 6 x 3
## country year population
## <chr> <chr> <dbl>
```

```
## 1 Afghanistan 1999
                          19987071
## 2 Afghanistan 2000
                          20595360
## 3 Brazil
                 1999
                         172006362
## 4 Brazil
                 2000
                         174504898
## 5 China
                 1999
                        1272915272
## 6 China
                 2000
                        1280428583
```

To combine the tidied versions of table4a and table4b into a single tibble, we need to use *left_join*, which you'll learn about later

```
tidy4a <- table4a %>%
  pivot_longer(c(`1999`, `2000`), names_to = "year", values_to = "cases")
tidy4b <- table4b %>%
  pivot_longer(c(`1999`, `2000`), names_to = "year", values_to = "population")
left_join(tidy4a, tidy4b)
## Joining with 'by = join_by(country, year)'
## # A tibble: 6 x 4
##
     country
                 year
                        cases population
##
     <chr>
                 <chr>>
                        <dbl>
                                    <dbl>
```

Wider

3 Brazil

4 Brazil

5 China

6 China

1 Afghanistan 1999

2 Afghanistan 2000

745

2666

1999

2000

1999

19987071

20595360

212258 1272915272

2000 213766 1280428583

 $pivot_wider()$ is the opposite of $pivot_longer()$. You use it when an observation is scattered across multiple rows. For example, take table2: an observation is a country in a year, but each observation is spread across two rows.

```
table2 %>%
  pivot_wider(names_from = type, values_from = count)
```

```
## # A tibble: 6 x 4
##
                         cases population
     country
                  year
##
     <chr>>
                         <dbl>
                                     <dbl>
                  <dbl>
## 1 Afghanistan
                  1999
                           745
                                 19987071
## 2 Afghanistan
                  2000
                          2666
                                 20595360
## 3 Brazil
                   1999
                         37737
                                172006362
## 4 Brazil
                  2000
                         80488
                               174504898
## 5 China
                  1999 212258 1272915272
## 6 China
                  2000 213766 1280428583
```

Exercises

1. Why does this code fail?

```
table4a %>%
  pivot_longer(c(`1999`, `2000`), names_to="year", values_to = "cases")
## # A tibble: 6 x 3
##
     country
                 year
                         cases
     <chr>>
                 <chr>>
                        <dbl>
## 1 Afghanistan 1999
                          745
## 2 Afghanistan 2000
                         2666
## 3 Brazil
                 1999
                        37737
## 4 Brazil
                 2000
                        80488
## 5 China
                 1999
                       212258
## 6 China
                 2000 213766
```

2. What would happen if you widen this table? Why? How could you add a new column to uniquely identify each value?

3. Tidy the simple tibble below.

```
preg <- tribble(
    ~pregnant, ~male, ~female,
    "yes", NA, 10,
    "no", 20, 12
)

preg %>%
    pivot_longer(c(male, female), names_to = "sex", values_to = "count")
```

```
## # A tibble: 4 x 3
##
     pregnant sex
                      count
                      <dbl>
##
     <chr>>
              <chr>
## 1 yes
              male
                         NA
## 2 yes
                         10
              female
## 3 no
              male
                         20
## 4 no
              female
                         12
```

Separating and Uniting

So far you've learned how to tidy table 2 and table 4, but not table 3. table 3 has a different problem: we have one column (rate) that contains two variables (cases and population).

table3

```
## # A tibble: 6 x 3
##
     country
                  year rate
##
     <chr>>
                 <dbl> <chr>
## 1 Afghanistan 1999 745/19987071
## 2 Afghanistan 2000 2666/20595360
## 3 Brazil
                  1999 37737/172006362
## 4 Brazil
                  2000 80488/174504898
## 5 China
                  1999 212258/1272915272
## 6 China
                  2000 213766/1280428583
```

To fix this problem, we'll need the separate() function.

Separate

separate() pulls apart one column into multiple columns, by splitting wherever a separator character appears.

```
table3 %>%
  separate(rate, into = c("cases", "population"))
```

```
## # A tibble: 6 x 4
##
     country
                year cases
                             population
##
     <chr>
                 <dbl> <chr>
                             <chr>
## 1 Afghanistan 1999 745
                              19987071
## 2 Afghanistan 2000 2666
                              20595360
## 3 Brazil
                 1999 37737
                             172006362
## 4 Brazil
                  2000 80488
                             174504898
## 5 China
                  1999 212258 1272915272
## 6 China
                  2000 213766 1280428583
```

Notice the column types: you'll see that cases and population are character columns.

```
table3 %>%
  separate(rate, into = c("cases", "population"), convert = TRUE)
```

```
## # A tibble: 6 x 4
##
     country
                       cases population
                  year
##
                                   <int>
     <chr>>
                 <dbl>
                        <int>
## 1 Afghanistan 1999
                          745
                                19987071
## 2 Afghanistan 2000
                         2666
                                20595360
## 3 Brazil
                  1999
                        37737 172006362
## 4 Brazil
                  2000
                        80488 174504898
## 5 China
                  1999 212258 1272915272
## 6 China
                  2000 213766 1280428583
```

Unite

unite() is the inverse of separate(): it combines multiple columns into a single column.

```
table5 %>%
  unite(new, century, year)
## # A tibble: 6 x 3
##
     country
              new
                      rate
##
     <chr>

```

In this case we also need to use the sep argument. The default will place an underscore (_) between the values from different columns

20_00 213766/1280428583

```
table5 %>%
  unite(new, century, year, sep = "")
## # A tibble: 6 x 3

Excerises

?separate

6 China

1. What do the extra and fill arguments do in separate()? Experiment with the various options for the following two toy datasets.

```
tibble(x=c("a,b,c", "d,e,f,g", "h,i,j")) %>%
  separate(x, c("one", "two", "three"), extra = "warn", fill = "left")
## Warning: Expected 3 pieces. Additional pieces discarded in 1 rows [2].
## # A tibble: 3 x 3
           two
                 three
     <chr> <chr> <chr>
##
## 1 a
           b
                 С
## 2 d
                 f
           е
## 3 h
                 j
```

```
## starting httpd help server ... done
```

The *extra* and *fill* arguments control what happens to the warning message and missing values when there are too many/not enough pieces to register into columns using *separate()*

2. Both unite() and separate() have a remove argument. What does it do? Why would you set it to false?

```
table5 %>%
  unite(new, century, year, remove = TRUE)

## # A tibble: 6 x 3
### A tibble: 6 x 3
```

```
##
     country
                 new
                        rate
##
     <chr>>
                 <chr> <chr>
## 1 Afghanistan 19_99 745/19987071
## 2 Afghanistan 20_00 2666/20595360
## 3 Brazil
                 19_99 37737/172006362
## 4 Brazil
                 20_00 80488/174504898
## 5 China
                 19_99 212258/1272915272
                 20_00 213766/1280428583
## 6 China
```

By setting remove = TRUE in both unite() and separate(), you will be excluding the input columns from the output. This looks much cleaner when you do this, hence why remove = TRUE is the default.

Case Study

To finish off the chapter, let's pull together everything you've learned to tackle a realistic data tidying problem. The tidyr::who data set contains tuberculosis (TB) cases broken down by year, country, age, gender, and diagnosis method.

who

```
## # A tibble: 7,240 x 60
##
      country
                   iso2 iso3
